CREW OF U. S. MARTIN "ROUND THE RIM FLYER"—Left to right: Colonel Hart, Lieuts. L. A. Smith and E. E. Harssen, Sergeants John Hardin, Jr., and Jeremiah Tobias

Martin Bomber No. 4 has been in constant use for a year at Bolling Field, Washington, D. C. With more than 16,000 miles of cross country work added to its credits, this plane was started off on an 8,000 mile flight around the rim of the United States, in command of Col. R. S. Hart. The colonel and his crew of four have just completed their remarkable pioneering trip.

Martin airplanes have demonstrated beyond a question the greatest time-mile efficiency of any aircraft yet produced, and are rapidly proving that the important centers of the United States can be connected by aerial transportation with but a few hours' flying.

THE FOLLOWING IS A COMPARISON OF A FEW ACTUAL FLIGHTS BY MARTIN BOMBERS WITH THE BEST RAILROAD TIME

POINT	TO	PILOT	DISTANCE	AIR SPEED	RAILROAD TIME
Cleveland	Dayton	Erie Springer	215 Miles	1 hour, 40 mins.	8 hours
Washington	New York	Capt. Peacock	220 Miles	1 hour	12 hours, 30 mins.
Cleveland	Baltimore	Erie Springer	300 Miles	1 hour, 30 mins.	14 hours
Cleveland	New York	Erie Springer	440 Miles	1 hour, 30 mins.	18 hours
Dayton	New York	Capt. Peacock	498 Miles	1 hour, 40 mins.	18 hours
Milwaukee	Washington	Capt. Peacock	600 Miles	1 hour, 15 mins.	18 hours

The superiority of performance which characterizes Martin Airplanes is the result of ten years of experience in building aircraft of a superior quality

FARMAN

AEROPLANES

Billancourt, (Seine), France

The FARMAN three-passenger "Tourabout"—the best French passenger plane to arrive in America. Now being demonstrated.

H & M. FARMAN planes have been the recognized leaders of the Aircraft Industry in France since 1907.

FARMAN planes have been flown by over 15,000 pilots, over the great capitals of America and Europe, in all kinds of weather, in Peace and in War.

H & M. FARMAN were first in the field in the construction of Commercial Aeroplanes with the Famous FARMAN "Goliath," making regular trips between Paris and Brussels.

FARMAN products are built for SAFETY, SERVICE and RELIABILITY, backed by the experience and knowledge gained in the manufacture of thousands of aeroplanes.

For business—Buy a FARMAN

The "Goliath"—14 Passenger (or freight)
The "Tourabout"—3 Passenger

Delivered at New York, planes assembled, tested, and ready for flight.

Our engineering department is at your service for consultation on aerial transportation problems.

GIBERT

We design and build propellers of walnut. Our mills are located in the choicest walnut districts in the country, affording an unlimited supply of the best timber.

Walnut is the acknowledged superior wood for airplane propellers, government tests having shown that it is strong, durable and able to withstand great shocks.

HARTZELL WALNUT PROPELLERS have proven by their performance that they are efficient and lasting.

Our Engineering Department will gladly co-operate with you in designing a propeller to meet your requirements.

HARTZELL WALNUT PROPELLER COMPANY

NOTE the angular contact of ball with raceway. Both radial and thrust loads resisted and are carried through the axis of each ball. Balls are always free to roll with practically no friction. No wedging. No cramping. No binding.

FREEDOM from wedging, cramping and binding of rolling elements eliminates excessive wear in New Departure Ball Bearings. No matter from what direction loads may come, or with what intensity, the Double Row carries them with greatest ease. Friction is practically eliminated.

Bearings which are made adjustable to "take up" for wear probably need that allowance. New Departure ball bearings will operate for the full life of the machine without wearing enough to require adjustment.

"Waldorf," designed primarily to attempt the Australian flight.

Known insurance men spoke of the good feelings which insurance people had as a whole towards aeronautics, and the effort they were prepared to put forth to help the industry in its mortal stages. They viewed it as a public duty, so Mr. Cowles thought, to take up aviation insurance even if the business were meager and unprofitable.

Now while we appreciate the kindness of these remarks and feel sure that the cooperatives of insurance companies would be a valuable help to the industry, we rather resent the patronizing attitude. Give the industry just a little more time, and aviation insurance will be a large source of profitable income for the insurance men, and a source constantly growing. Instead of patronizing the industry, insurance companies would do better to study the subject more closely, to give a hand in seeing that certain well known precautions in structure and photon are always observed. Their differential action in granting insurance only at certain ships, with well qualified pilots, and to entirely respectable operating companies would be extremely helpful in keeping the industry on an entirely steady basis.

Breach Effect on the Air

News has just arrived of the successful termination of a flight from England to Australia. On a route following Paris, Lyons, Rome, Naples, Brindisi, Sicily, Alexandria, Rhodesia, Bagdad, Basra, Karachi, Delhi, Calcutta, Rangoon, Peking, Singapore, Batavia, Agostoia and Port Darwin, more than half the ports of call are British possessions.

A similar flight might be made from the Cape to Cairo. A huge British flying boat might fly from Ireland to Canada, and be on British territory on both sides of the ocean.

There is nothing remarkable therefore that the British people as a whole, and the British Government in particular, should devote much attention to aerial work, and devote such large sums to its development.

As in the case of the Merchant Marine, the United States will have to meet the mighty yet almost unconscious British effort, with a determined and conscious effort.

Cockpit Design

It is interesting to see how rapidly the art of cockpit design is developing.

An interesting example is the cockpit of the Sepwip-

"Waldorf," designed primarily to attempt the Australian flight. The pilot's and navigator's cockpit is fitted with Triple side windows and a floor window in front of the seats. Normally the seats allow the crew to sit in the usual position with their heads just clear of the cockpit, but provision is made by means of which the cockpit may be converted into an enclosed cabin, the seats being fitted with slips which allow them both to drop about a foot and sliding doors being pulled across the openings. None of the side windows are made to open, and a pipe running from the front of the radiator supply fresh air to the crew. Dual control is provided, and the pilot has two smaller bars one above the other, for the two seat positions. There is a system of pull-out tables for charts and slate for instruments. The circular opening for the pilot's head is fitted with an aluminum bending which is graduated off into degrees for use with a sextant. In rear of the passenger are cupboards for food.

It would seem quite possible even in a small single-engine machine to design a cockpit providing every facility for piloting and navigation, which is thoroughly comfortable and flexible.

Parachutes

E. H. Calthrop, the well-known designer of parachutes, suggests that the worst enemy of the parachute is the presence of protrusions in rear of the canopy on which the parasite may run free. The parachute, however well designed, is always a delicate affair, and even a small rent may cause disaster. If the tail end in particular presented a smooth unbroken surface, there would be much less chance of accidents. Mr. Calthrop suggests very firmly that in the design of military machines definite specifications be laid down to require protrusions in rear of cockpit, and his suggestion is worth consideration, particularly in view of the authority that he expresses warrants.

Water Resistant Plywood Glues

In a recent issue of AVIATION, a description is given of tests for waterproof glues developed by the Forest Products Laboratory.

To read of the rigid tests now imposed, and necessarily met, is most reassuring to the airplane constructor. The Forest Products Laboratory considers 8 hour boiling and ten day soaking tests as quite reasonable, while the boiling tests producing more severe damage.

Such tests, it is safe to say, are much more severe than anything that glues will have to withstand in real practice. They indicate tremendous progress since the early days of glue manufacture.

Explanation of Peculiarities Observed in Flying in the Wind

By J. G. Collin

Associate Director of Research, Curtis Engineering Corporation

Considerable misconception exists as regard to the effect of wind on machines which float or fly in the air.

The misconception arises principally as not distinguishing between the effect of the wind on the machine and the effect on the speed of the machine relatively to the ground, and as not having a full realization of the fact that forces are only produced by changes in velocity and not by velocity itself.

A steady wind is determined only in so far as it is reduced to the ground. It is not determined in the air because there is no change in velocity and no force is generated.

The effect of a steady wind on the ground speed of a platform is more if it is turned into a tail wind than is opposite to the flow speed of the plane, thus reducing the strain on the leading gear due to high relative ground speed.

An airplane flies relatively to the wind, whatever the wind velocity may be. The steady horizontal wind which it experiences is not the same as the steady horizontal wind which it obtains by a definite relative speed between the plane and the air far away from the surface.

The atmosphere is carried around by the earth at a speed which is constant over the entire planet, except at the poles. To all intents and purposes this is a sort of tropical cyclone, and yet we are secondary to it because we are all moving with it and hence are at rest relatively to it.

What is commonly called a wind is a relative motion between the earth and the atmosphere above it. It is felt as a wind because everything, excepting those objects in the air, are moved more with it.

FIG. 1

As a consequence, as long as it is in contact with the ground it has to fly in the wind, unless it is able to leave contact with the ground of its own accord, of course. Were it not that the pilot can run his drift relatively to the ground, he would not feel could not be aware of any wind excepting that produced by his own motion through the air necessarily, in the case of the airplane, for compensation. In the case of the airplane, as in all other cases, the air is. These remarks refer to a uniform and steady wind ratio.

When the wind is variable or gusty, naturally different phenomena arise. Changes in wind speed, especially abrupt ones, and even distinctly felt, often produce dangerous disturbances. Changes in wind speed, however, particularly the change as taking place and so long, although these effects may last for a longer period. The speed of the wind before and after the change is of secondary importance, the magnitude of the disturbance depending on the rate of change of wind and the duration of the change.

The change of air velocity relatively to the ground can always be estimated by the vectorial addition of the velocity relatively to the air and of the velocity of the air relatively to the ground. In a steady horizontal wind, as far as the plane is concerned, there is no effect and can be no reason for any peculiarity in its creation.

An apparent exception to this statement is in the instance that if a pilot judges his air speed by his eyes of the ground, when flying in a wind, he will be misled and since he

may and know the wind speed he may commit serious errors of control, especially on landing and in maneuvering. That is, however, purely psychological and is not pertinent to the subject.

Now, start from any such explanation, since it is possibly assumed that production of control do occur in a steady wind that do not occur in calm air and that experienced pilots provide for them, the reasons for such previous trial is not clear for the moment. There are two principal possibilities to consider:

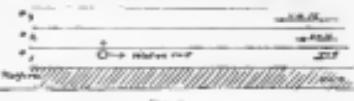

FIG. 2

1. A vertical wind gradient exists—meaning by this that the horizontal wind speed changes with the height above the earth's surface. This change is usually an increase.

2. A more or less gradual horizontal variation in wind speed exists, the wind being steeper in the sense of Case 2 is not amenable of any mathematical treatment¹ and is, in addition, the possibilities we are attempting to explain occur even when the wind is blowing steadily. We shall then limit ourselves to the consequences of Case 2.

It is possible to have different horizontal velocities of different altitudes and the plane must rise or fall in order to compensate the effect of any variation of wind velocity. As the pilot is continually changing his level in flight, either consciously or unconsciously when making turns, climbing, etc., he will be able to adjust his altitude to provide that he need not necessarily be subjected to any variation.

The immediate problem then reduces itself to finding the effect on the rate of climb in a wind which has a velocity increasing (say) with altitude according to some law. It is, of course, well known that as altitude increases the wind naturally does increase with height, the observed effect being most

FIG. 3

markedly according to friction with the earth's surface. The distance of the wind from the ground changes. Changes in wind speed of 20 mph per 1000 ft. rise and of over 90° in deflection are not unusual. We shall, however, consider that

¹ In regard to this see work of R. H. Myers, Theory of an Airplane Flying Crosswind, Part I, Aeronautical Research Institute, California Institute of Technology, Vol. 20, No. 1, April 1937, and the following article in the Bulletin of the National Advisory Committee for Aeronautics, Vol. 31, No. 1, October 1937.

merely a speed change takes place. It is also evident that the speed change per ft. rise can and does vary at different levels, but for purposes of calculation we shall assume that the wind speed increases at a uniform rate per ft. rise.

Effect of a Wind Gradient

Consider an airplane climbing with speed V along a flight path, that path being an arc, with a radius of curvature R , so that the wind speed is constant at a rate of v' feet per second per ft. rise. The quantity v' is called the vertical wind gradient.

The lateral speed of the machine is $V \sin \beta$ ft./sec. (1) and the longitudinal speed is $V \cos \beta$ ft./sec. (2) where β is the deflection angle and $\beta = \tan^{-1} v'/V$. (3) This last expression is the acceleration in the direction of wind velocity due to

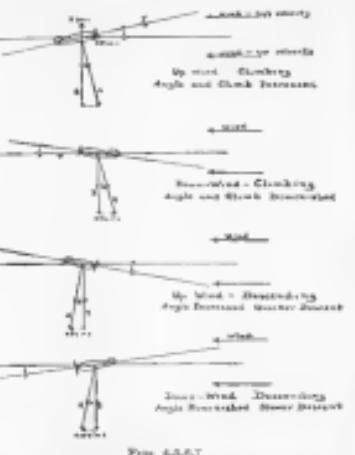

FIG. 4-A-E-T

a rise. This acceleration acts on the plane just as if the plane, flying originally in calm air, were to experience an increase in wind speed. It is evident that if v' were large that either way the result would be an improved lift, and if it were during the other way the lift would be decreased.

Thus, in other words, an apparent horizontal acceleration of the plane which is in the direction opposite to the wind velocity when the plane is going from low speed wind to higher speed wind and which is in the same direction as the wind when going from high speed wind to lower speed wind.

Thus, matter which is familiar to us, perhaps to more easily understood, by the following analogy:

Consider a number of moving platforms, Fig. 2, each as here been proposed at various times for safety interpretation. Let the platforms be three feet wide and each one have a speed of 8 ft./sec greater than the preceding one. As it is, in particular, easy to step from the first to the second, Fig. 2, and to step from the second to the third, Fig. 2, the lift is increased. He starts to climb down, the plane decelerates rapidly, it goes lost in lift and comes to rest.

Consider now what happens when a heavy load is carried on a platform. The platform is not as fast as the one just before it and the greater weight increases it at a speed of 8 ft./sec per amount of its weight it is not immediately carried along by the platform, or, what is the same thing, the speed has been increased in the direction opposite to the motion of the platform. It is, in other words, lost in lift. If it is, in fact, lost in lift at the rate of 8 ft./sec , we can say that the load receives an acceleration relatively to the platform, where it is at any instant, of 8 ft./sec^2 . This is the kind of quantity represented by (3). The direction of this acceleration is opposite to the motion of the platform.

Consider what would happen to yourself in stepping from one platform to the next one moving faster. Unless you especially prepared yourself you would fall sideways, lose balance, fall to the side, etc., and experience a loss of the platform. In other words, when you fall from one platform to another you receive the equivalent of an impulse on your body directed against the plane, same you fall with your head pointing in that direction. It is an impulse because the change in speed is sudden, and the time of action is small and the force is correspondingly large, of course, of course, the impulse would become more nearly a uniformly acting force.

Now, as long as an impulse is directed against the wind resistance, the effect of it is to increase the lift, to reduce a force and consequently this is why a wind speed does good. The lift is increased and resistance increased as on the plane goes into faster moving air and the climb is improved.

On the other hand, an increase in wind speed causes the body to move more rapidly, the accelerations are all increased.

Besides the accelerations just described, which acts on the plane, there is the acceleration of gravity. These two accelerations combine into one condition of motion:

$$\ddot{x} = V \dot{\gamma} + \frac{g \sin \beta}{V} \quad (3)$$

which makes an angle

$$\theta = \tan^{-1} \frac{g \sin \beta}{V \dot{\gamma}} \quad (4)$$

with the vertical. The plane flies relatively to the resultant acceleration \ddot{x} just as it previously in calm air, but with respect to the acceleration of gravity.

If the plane climbs at an angle $\beta > 90^\circ$ with respect to the vertical (4), it can climb at this same angle (very approximately) with respect to \ddot{x} , which is all intent and purpose because the new relative vertical.

Figures 4, 5, 6 and 7 show the direction of the resultant wind acceleration for a plane descending, a plane climbing down-ward, a plane descending up-ward and a plane descending down-ward, a plane descending up-ward and a plane descending down-ward, respectively—up-ward meaning flying with the wind, down-ward, flying with the wind.

Fig. 4 Climbing against the wind: The plane goes into faster moving air. The angle β is increased by b and the plane does not climb.

Fig. 5 Climbing with the wind: The plane goes into faster moving air. The angle β is increased by b and the plane does not climb.

Fig. 6 Descending against the wind: The plane goes into slower moving air. The angle β is increased by b and the plane descends at a steeper angle.

Fig. 7 Descending with the wind: The plane goes into faster moving air. The angle β is decreased by b .

Consider Cases 4 and 5. A pilot starts to climb; the plane sets off quickly and climbs bodily. The lift is diminished. He starts

be decreased, the plane tends to fly horizontally and to depress the elevator in order to decrease speed rapidly.

Say now while descending he has descended and as soon headed into the wind. Case II comes into effect and the pilot has to depress the nose of a perhaps alarming angle.

It must already be quite evident that the material would seem to act quantity to a piled material of the reasons for such behavior.

Effects to Be Expected on a Turn

Suppose that a plane flying horizontally and upward makes a turn, either to the right or left. In both cases there is a tendency to downward. The turn produces a drop, hence the plane goes from horizontal flight upward, normal condition, case Case II. The usual drop is measured.

A plane flying horizontally downward, normal condition, makes a turn, either to the right or left, up-ward. A turn produces a drop, hence the plane goes from normal flight into Case II. The usual drop is measured.

When the turn 90° of a turn has taken place a corresponding drop is also taken place and the plane gets a reduced amount of lift, which is due to the effect similar to the one given to a plane flying normally.

If originally flying up-ward, a 90° turn produces the reverse sort of an up-ward pull.

If originally flying down-ward, a 90° turn produces an up-ward pull.

Numerical Results

Referring to equation (4) defining δ as the change in the angle α so small we can take this small angle to be the same as the angle β , we find that the percentage change in moment due to turning is directly instead of the rate.

Show them exactly:

$$\tan \delta = \frac{V^2}{F}$$

we can write approximately

$$\delta = \frac{V^2}{F}$$

and, therefore,

$$\delta = \frac{k}{F}$$

which is the fractional change in changing angle due to wind gradient k .

F is in m.p.h., per 1000 ft.

V is in m.p.s.

and $g = 981 \text{ ft./sec.}^2$, we may write this expression as

$$\delta = \pm 0.00075$$

For example, if the wind increases at the rate of 30 m.p.h. per 1000 ft. and the plane is traveling at the rate of 100 m.p.h., the percentage change between climb up-ward and climb down-ward is a fraction of

$$2 \times 30 \times 100 \times 0.00075 \\ = 30.0\%$$

The difference in climb up-ward and climb down-ward for the same conditions is 13.4%. If the plane travels at 50 m.p.h. under the same conditions the percentage change becomes 20%, instead of 15% and 45% instead of 36.8%. It is apparent that the effect of the wind on the plane can be utilized to the maximum.

If it is assumed that the wind has periodic increases and decreases in horizontal speed at any given level it is seen from the foregoing that by proper conserving the energy can be shown as to prevent the effect of the wind on the plane from decreasing to zero, in which case only the effect of these changes by the "feel" of the pilot and could only utilize these after long experience, if at all. Hence probably are instances able to adapt their flying attitude to these varying conditions and still maintain a safe altitude. However, it is difficult to imagine a situation where with a large airplane it would require that the cross section of the disturbance be large or larger than the airplane.

Forces and Moments Brought Into Play on Banking

There are still other actions taking place while making a turn in a wind in which there exists a wind gradient.

changes of a road on an automobile and are probably due to sudden small changes in wind speed or wind direction, or both.

As a slight change in vertical wind direction suddenly modifies the lift it is easily understood that a sudden drop or rise will tend to take place, and as soon as the plane passes through the disturbance it regains the even level of the wind. This is the effect of the "feel" of the pilot of a fairly large aeroplane three or four times as much as that of a smaller aircraft. The result of the passing by the plane of a fairly large area is such that there is either a sudden shifting of the vertical wind direction downward, producing not only a drop due to the downward component of the wind velocity, but also a decrease in lift due to the greater angle of attack, and a sudden drop in air temperature, this producing a corresponding change in air density and causing a sudden change in lift. This is a change of the temperature change in a rise. These two factors can also act simultaneously.

To prevent this effect it is thought appropriate to realize that a check on the following is the pilot of the possible cause of perturbation is absolutely necessary. This under standing is as necessary for the air pilot as it is for a car driver to know whether, for instance, that a car is liable to skid on a turn, that the percentages are likely to be higher. The knowledge of these factors is a valuable factor in determining what is occurring and the reasons therefor, as well as indicating the proper measures for overcoming their detrimental effects and utilizing them for his advantage.

FIG. 8

As seen in the diagram, the pilot sees an opposing couple FV^2 tending to increase the bank and sharpen the turn.

After the next turn of 90° to fly with the wind the couple disappears (or two others make their appearance), one due to the wind gradient, and the other due to the fact that the machine is on the higher or ground or the lower, the machine tends to yaw the machine slightly to the point's left, and the other due to unequal lift on the right and left wings, the lift on the upper being decreased and on the lower increased relatively. The machine tends to under load the machine and is a righting moment.

Consider an airplane flying with the wind whose banks while making a turn to fly across the wind.

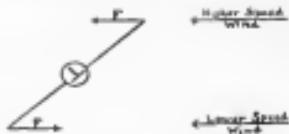

FIG. 9

This however brings into existence a couple FV^2 tending to right the machine and makes the turn easier.

After the next turn of 90° to fly with the wind the couple disappears (or two others make their appearance). One due to unequal drift leading to yaw the machine towards the point's right and the other due to unequal lift, which is greater on the higher than on the lower wing, which is due to an opposing couple and tends to make the turn sharper. The resultant effect due to the pilot is made up of these two apparently opposite effects. There are however no corrections to one end but that these effects produce the perturbation felt by all pilots when entering in the wind.

It should also be noticed that the relative value of these effects changes with the size and weight of the machine being turned.

ough calculations were made of the magnitude of these couples for a machine of 90 ft. span, equal radii of 8, weighing 3,000 pounds for a 50 m.p.h. per 1,000 ft. and an angle of bank of 45°.

The cross wind couple is negligible. The couple due to unequal lift gives a value of about 130 lb.-ft. The turning couple due to unequal drift shows 18 lb.-ft.

Pumps and Air Holes

The holes which are usually always left in a machine in flight are somewhat of the same nature as the effect of un-

derstanding.

Development of a 15-Foot Airplane Wing Rib

By Raymond M. Works*

During the progress of the war the Forest Products Laboratory of the United States Forest Service, Madison, Wis., at the request of the Bureau of Aircraft Control and Safety, Army Department, undertaken the development of an airplane wing rib of maximum weight, bearing a closed length of 15 feet, and capable of sustaining, without rupture, a distributed load of 670 pounds.

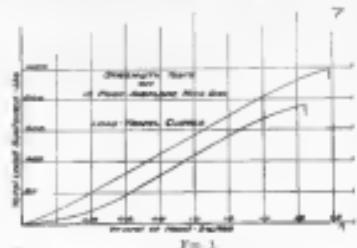

Fig. 1

Two distinct forms of rib were investigated at the laboratory as possibilities for development, namely, one having a plywood web, the other using some form of truss to carry the load. In the former type the web section was made of shiplap wood with adjacent planks placed at 90 degrees to each other; in the latter, various truss designs were tested.

Method of Test

Ribs for each design were tested under long-spared load distribution, and a few ribs of the final design were also tested under biaxial load distribution. The distribution diagrams shown in Fig. 2 were used.

Diagrams of 90 degrees represent the sum of the unit lift pressures on the upper and lower wing surfaces. The expansion used for applying load to the ribs is shown in Fig. 18. By dividing the basis of the diagrams (Fig. 2) into 12 equal distances and extending vertical lines upward, each diagram is

divided into 12 areas. The 12 concentrated forces applied to the rib are produced by the sum of the unit lift pressures which are distributed in circles. The downward motion of the movable head of the machine causes the load to be applied to the rib. To approximate the lateral stiffening the rib receives from the wing covering when it is service in the airplane, the top

* Associate Professor in Forest Products, Forest Products Laboratory, U. S. Forest Service, Madison, Wis.

green deflections. Fig. 3 shows two typical load-travel curves, the upper curve being that of a Warren truss rib and the lower that of a twisted-truss rib. The lower curve looks softness at low loads because of initial slackness in the Warren truss members. The upper curve shows the effect of more rigid construction.

Besides stiffness, the curves show the total load resistance, the work necessary to cause failure can be determined by the integration of the area under the curve.

To obtain maximum efficiency from the wings when flight is in consideration, the load must be applied in 120° or 180°. That is to say, either the highest stiffness or the rib showing

Description of Ribs

Some types of ribs involving 13 different designs were tested: plywood, wrapped-wire strip, twisted-wire strip, Warren truss, Vierendeel, Pratt truss, Warren truss, and double Pratt truss. A key to these various ribs is given in the following tabulation:

December 1, 1929

AVIATION

spent more time in construction than some of the other ribs having equally good strength and weight values.

Pratt Truss Rib—From previous tests on conventional 15-foot wing ribs of the Pratt truss type it was found that the strength of the joint between the diagonals and the cap plates was almost wholly dependent upon the glass, the screws encumbering

only be perceived from an air doing by a difference of pressure on the two sides of the displacement on the manometer. It is this difference of pressure which is indicated on the manometer and shows a right or left-hand turn.

All turns, however, are banked, and this assumption is only made to make the air easier to understand.

If we now consider a banked turn and assume that the airplane is located at the correct angle. By the correct angle is meant an angle which causes no side-slip, that is, such an angle that the apparent direction of gravity (that is the resultant of gravity and centrifugal force) is at right angles to the plane of the turn.

As a result of the forces acting on the air or the turn, 2. As the banking is at the correct angle, the resultant of gravity and centrifugal force act at right angles to the direction of the turn and have no effect.

3. The pressure against the inside of the turn clearly has no effect.

4. The atmospheric pressure at the two static heads is not equal; as the airplane is banked, the outer end is higher up and at a place where the air is at a low pressure. The differential manometer will show this difference of pressure.

On the other hand, the two static heads are at the same height, so that the two pressures are different. The forces resulting from the turn are also different.

5. Gravity acting on the air in the turn. As the turn is banked, this will tend to make the air flow noseward.

2. Atmospheric pressure at the static heads. As the pressure at the outer end is less than at the inner end, these pressures are not equal and the air will flow from the boundary of (1) and (2) across them. If equal and in opposite directions, and the combination of the two will have no effect.

3. The pressure against the inside of the turn clearly has no effect.

4. Centrifugal force is the only remaining force, and this clearly will cause a difference of pressure on the two sides of the displacement of the manometer. Although these two ways of considering the forces which act on the air in the turn are so different they are both correct.

V = the speed of the airplane.

θ = the angle of the turn in which it is flying.

b = the distance between the static heads.

ρ = the density of the air.

P = the differential pressure on the air required to prevent the increment along the air tube.

β = the angle of banking.

With reference to Fig. 1, an air-slip and the air tube or the vertical plan passing through the center of the circle

$P = \rho V^2 \cos \beta / r$.

Usually β is the correct banking angle, then the $P = \rho V^2 r$. In order to make P large r must be large. As the density of

The Linke-Hoffman Central Power Plant Giant Biplanes

By Eric Hildebrand

Some detailed information is now available of the giant airplanes built by the German Linke-Hoffmann works, especially a central multiple engine power plant with a single or twin tractor.

The LHB1

It appears that the first Linke-Hoffmann model (LHB1), shown in Fig. 1, was of an unsuccessful character. The

FIG. 1. FRONT VIEW OF LINKE-HOFFMANN LHB1.

and failure of engine mountings, leading to destruction of the wings, characterized.

Figure 2 shows a good view of the front cockpit in the nose of the machine. The engine of the LHB1 and the front-panel roof is clearly visible.

The LHB2

In the LHB2, which was decidedly more successful than the LHB1, there were a number of important modifications. Fig. 3 indicates very clearly this latter model possesses an entirely different and more modern airframe, and Fig. 4 gives an excellent rear view of this machine. It is interesting to com-

FIG. 6. BLERIOT BIPLANE SIDE-SHOCK AEROPLANE

mission system of the L.H.R.L. it exhibited many new ideas, the outstanding feature being the use of a single tractor motor and the general resemblance to an ordinary tractor biplane.

Even the two-wheel rear gear of Fig. 6 is nothing but an enlarged edition of ordinary airplane practice. It is efficient and not without likelihood that the large size of the wheels enables them to pass over ditches without danger of the aircraft overturning. A writer not so posted by the Germans, when in aerial fighting in using the aeroplane, the pilot would sit on a single seat, and when two seats were passed without overturning, the plane finally coming to rest with the pilot's undivided 100% in the marsh. Fig. 6 shows the very logical placement of the side shock absorber. The credit to which the Germans were driven due to lack of

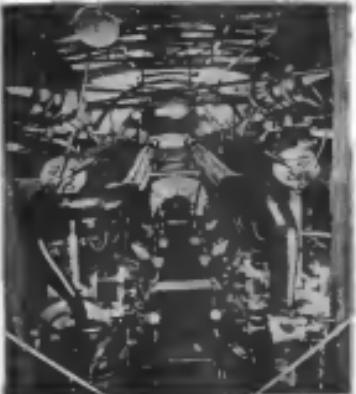

FIG. 7. ENGINE AND GRAVITY TANK MOUNTINGS

material or knowledge of the L.H.R.L. it exhibited many new ideas, the outstanding feature being the use of a single tractor motor and the general resemblance to an ordinary tractor biplane.

It will be noted that the somewhat peculiar construction of the tail surfaces of the L.H.R.L. with a monoplane stabilizer and double elevator, has been replaced by the biplane stabilizer and elevator of the L.H.R.L.

The rear part of the fuselage has a transparent covering to enable ready inspection of controls.

Little information is available regarding the transmission between the four engines and the single screw. Apparently the various engines transmit their power to one shaft, which, after passing a single transmission gear wheel, drives the main propeller.

Figure 8 shows the enormous pilot's cockpit with dual control, looking into the engine room.

At a speed of 220 kilometers there is a fuel capacity of 10 hours with a load of 2 pilots, machine gun and navigating with their luggage and necessary instruments. For con-

mercial aviation the Lohner-Hoffmann R2 model is now provided with an enclosed cabin for 12 passengers aft of the pilot's cockpit.

Vastous advantages are claimed for the central power plant installations as compared with the airplane power plant installations, such as the absence of side obstructions

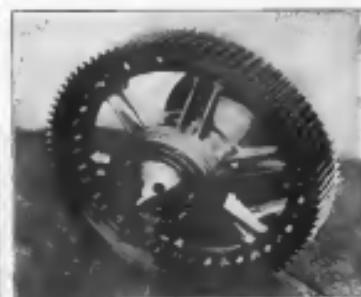

FIG. 10. ENGINES AND GRAY TANK MOUNTINGS

for vision and gas range, the decrease in number of members, since one machine can now take care of all four motors, a more complete understanding between engineers and pilots. The central power plant with single screw has a saving in weight as compared with the push-pull type, and the few parts of it are made strong. The main tuning procedure can be made very efficient. There is almost infinite reliability in the power system.

Book Review

BIG AIR AIRPLANE IN BRIEFS, by Stanley Baldwin, 223 pages. Aeroplane and General Publishing Co., London. £1.— net.

This book appeared originally as a series of articles in the *Aeroplane*. Mr. Grey, the writer of the introduction, states that Mr. Baldwin has an intimate knowledge of detail work. We can thoroughly endorse this opinion.

At first it might be thought that this was merely a description of the *Big Air* in the most general manner, as a matter of fact it is a thoroughly practical and most comprehensive manual of airplane construction. We must admit any it is the first work of its kind in the airplane field.

The author describes the most practical way of building airplanes, showing space gains, detail constructions as to 20%, assembly, strength, and flying out. The text as illustrated with the best kind of sketches.

Wing covering and shaping are treated somewhat sketchily but this is more than made up for by the careful remarks on general form and dimensions.

A great many of the previous types which it takes as examples will prove to be found in this little book.

HYDRO BOAT INVENTED AT ALBANY ON GRAHAM HILL REPORTED TO MAKE 12 MILES PER HOUR. LENGTH UNKNOWN (C. D. INTERVIEWED)

Resume of Wind Tunnel Tests of Airship Envelopes

By J. C. Hunseker, Eng. D.

A large number of stream-line bodies have been tested in the 6-ft. wind tunnel at the Washington Navy Yard, and without going into detail of the results certain conclusions of general interest have been reached.

The resistance is in a relative way of velocity V is expressed by the formula:

$$R = C C_0 g \left(\text{Volume} \right)^{\frac{1}{2}} V^2$$

where C is a constant, C_0 the density of the air and g a coefficient and V the velocity. The form of the body is such that C has the low resistance for given volume or length. This expression was first proposed by Prandtl and is in general use.

In the course of tests on various forms, the coefficient C has been found to vary with the shape of the nose as well as the quantity V in which the body moves. From discussions thereof, the resistance can only vary as V^2 where the resistance is caused by skin friction. Good stream-line forms have a minimum of skin friction and skin friction has a relatively large effect.

In fact, for seven models of very different shapes, representing seven aerodromes, the skin friction computed by Zemke's formula, $0.0000754(V)^{1.75}$, amounts to from 10 to 15 per cent of the total resistance observed.

The coefficient C appears to vary between $V^{-0.5}$ to V^{-1} .

The drag ratio or ratio of total resistance of model to the model scale varies between 15 and 27.

The resistance at constant air speed appears to vary not as V^2 , but as V^1 for larger power. Indicated models show a maximum between T_{\max} and T_{\min} .

Testing moments determined for several models indicate practically no difference for small angles. It appears to be immaterial what form of law is used within reasonable limits.

The shape of the end section has the most important effect on resistance. Bow and stern are less important. A pointed middle body is disadvantageous, and for a length added equal to diameter may increase resistance 10 per cent.

The form of bow is also very important than the stern. A flat bow is replaced by a bow in the case of a ship without change in resistance. A long, fine or pointed bow is much worse than a shorter, rounded one of equal surface.

A flatbow section between 5 and 6 appears more advantageous.

The above ratios apply only to good forms.

The form factor varies in resistance, depending on shape, not more than 5 per cent above or below the average of the series.

MAYNARD LOSES TO DONALDSON

TWO RECORDS ESTABLISHED

Captain Averages 106 Miles an Hour; Covered 823 Miles in Day.

Although Ernest Maynard, Jr., Maynard, the "Speed Doctor," was the first aviator to fly from Minot to California in 1919, he has now established several records, as unofficial calculations of his flying time and time of flight over various distances have been made public in the recent days.

It is estimated that Capt. J. G. Donaldson, second to return to Minot, and the first to make the trip in a new Kinner K-5, in one hour and 15 minutes, equipped with a 160 horsepower American-built Hispano-Suiza motor, which has a maximum power of 4,000 miles, in 45 hours, 45 minutes and 45 seconds. This record was set up at 106 miles per hour, or 106 miles and 10 seconds.

In computing his time, however, there must be added a period of eight hours, which he was on the ground before and after his flight, changing his motor.

Capt. Donaldson, a veteran flier of the west, ***** left Grand Junction, Colo., two weeks ago to take part in the annual air meet at Cheyenne, Wyo., covering the 8,400 miles at an average speed of 108 miles an hour, and the other 100 miles in 10 hours and 45 minutes, or 10 hours and 45 minutes when he flew from Rock Island, Ill., to Minneapolis, Minn.

Maynard's Other Records.

Besides those records Capt. Donaldson also has the distinction of being the only aviator to make the 1,000-mile trip from New York to San Francisco without refueling at one stop. The engine worked like a charm all the way, and it was not even necessary to change a bushing along the

Air Fans for Driving Generators on Airplanes

By Capt. G. Francis Gray, U. S. A., Lt. John W. Reed, U. S. A., and P. N. Elderton
Engineering and Research Division, Radio Development Section, War Department, Washington, D. C.

In this paper the authors first briefly describe the method used by the Radio Development Section of the War Department in testing air fans used for driving the airplane generators usually installed on airplanes for radio communication. They next discuss the mean length of various types of air fans used during the war and present numerous photographs and curves clearly illustrating their construction and performance.

The difficulty of the problem lay in designing a fan which would run at constant speed in the air streams of widely varying speed set up by the airplane in flight. The various types of fans tested were: Flat-blade fans of special design; flat-blade fans with solid and hollow cylindrical regulating vanes; flat-blade fans with a friction clutch or a belted brake centrifugally regulated, and propeller-blade fans in which the pitch is centrifugally regulated.

During the war numerous air fans made of carbon telegraph and telephone apparatus or military supplies, and the problems of power supply for such equipment received a great deal of attention. The possible sources of energy may be listed as follows:

a. Storage batteries or dry batteries.

b. Generators driven from the airplane engine, with or without cooling storage batteries, and supplying the radio sets directly or through dynamos.

c. Generators driven by separate engine.

d. Generators driven by air fans as "windmills" placed in air streams outside the airplane fuselage.

From an economic point of view, method d is preferable. It was seriously considered, but was not adopted because of inherent disadvantages in operating independently, and also because it delayed mounting the generator. The authors believed that of our Allies, principally the French, in the war did method d, mounting the generator outside the airplane fuselage and driving it with an air fan.

The work done in the development of air fans for this use was carried out by the Radio Development Section of the War Department, and the results obtained under the direction of Capt. G. F. Gray, who was directed by the War Department to conduct investigations, was often fragmentary, and unguided investigations, the result of which was evaluated but for which funds and personnel were not available. This report is presented with the work still in its earliest form in the hope that results obtained may be of value to others who are endeavoring to carry out further investigations on the problem.

Conditions for Which the Air Fans Were Required

Two types of generators were to be driven by the air fans that were desired to develop. The essential data on these are as follows:

Generator for Radio Transmitter Sets	Generator for Radio Receiver Sets
Generator output, watts	4000
Generator output, watts	1000
Generator output, watts	400

Method of Test

Previously all of the tests described in this paper were made with the wind tunnel of the Bureau of Standards. The wind tunnel was used to obtain the required materials for exploring them. A special testing generator was mounted in the wind tunnel and the fan to be tested was attached to it. The generator was provided with a magnetic tachometer, a separately excited field, and conventional means for applying load to the generator shaft.

The external shape and size of the fan were determined by the Bureau of Standards. The fan had to be able to withstand the maximum wind velocity, with which the air fans were to operate in service, and with this generator and the regular wind-tunnel equipment for measuring wind velocity, tests could be made rapidly and accurately.

All of the air fans considered in this development have

by courtesy of the American Society of Mechanical Engineers.

normal speeds of 4,000 r.p.m. or above, and the unregulated fans had very low torque characteristics. Therefore, it was necessary to provide an over-speed test to provide the wind tunnel load. For that purpose a 30-lb. motor operating through a

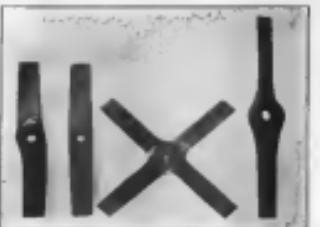

FIG. 1. PRE-WAR AIR FANS

clutch belt drove the generator shaft to a suitable shaft extension for the fan to run up. The fan was capable of driving the air fan at speeds up to 14,000 r.p.m. and to prevent the fan from going too fast, a limit switch of the "no weaker pitch" type was provided by a replaceable metal-shielded switch. Failure at this point mostly resulted in the breaking of the replaceable shaft extension and of course the destruction of the fan, without injury to bearings or generator parts. Unrepeated the flying fragments from such a failure were often fragmentary, and exploded investigations, the result of which was evaluated but for which funds and personnel were not available. This record is presented with the work still in its earliest form in the hope that results obtained may be of value to others who are endeavoring to carry out further investigations on the problem.

Conditions for Which the Air Fans Were Required

Two types of generators were to be driven by the air fans that were desired to develop. The essential data on these are as follows:

Generator output, watts

provided with wings, pins or other projections which are normally enclosed in a room in the blade, but which are caused by centrifugal force to emerge and so retard the rotation of the fan. They have the disadvantages of low efficiency and consequent high head resistance, but were considered worth trying. Fig. 6 shows various development models.

FIG. 6. FIXED-BLADE FANS WITH WING BLADES

Round rods, rods with slots and metal webs, flat strips, etc., were tried for the moving blade-blade. Many showed promising results, but each was the type in which the little slots were provided and moved out into the air by the action of centrifugal weight. Another interesting fan had the blades arms actuated not by centrifugal forces, but by air pressure on a plane mounted at the end of the arm of the fan, and gave a very good result, for a certain range, the figure actually decreased with increase in air velocity.

The next conclusion from this research was that the wood-blade propeller would give fairly good characteristics over a

FIG. 7. TYPE FA-6-A, VARIABLE-PITCH AIR FAN

limited range of air speed, and with further refinement it might have been worth putting into production. However, that stage was never reached, due to the work on the pivoted-blade type of fan described below.

Pivoted-Blade Air Fans. As in the types of regulating air fans discussed above, the feature of this pivoted-blade type is the mechanical simplicity and consequent low cost of these low efficiency and consequent high head resistances. They offered a possible solution, however, and were tried out experimentally. In the friction-shaft type of fan the fan has no capacity of five revolutions about the shaft of the generator, which it drives through a gear set. The chief idea is to reduce the capacity of centrifugal reaction when the fan passes the predetermined position, preventing the fan to run at higher speed than the driven shaft of the generator. The curve of this fan was satisfactory for the

first model, but the lossing due to slipping of the clutch at high velocities was too great to permit the use of the fan in practice and the development was abandoned.

In the second-blade type of fan the fan is keyed to the generator shaft and rotates with the motor, being held in place by a bracket suspended by a centrifugal weight and bearing on a plate mounted on the generator frame. This also was tested and gave results essentially similar to those obtained with the clutch type. With the very considerable variation in air speeds, the effect of the friction devices generated some heat that their use was discontinued.

Pivoted-Blade Air Fans. The ideal principle for the design of a regulating air fan is that of varying the pitch of the blades to correspond to the variation in air speed, thus gen-

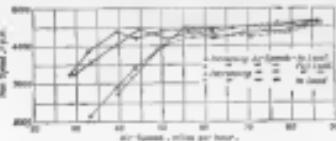

FIG. 8. PERFORMANCE CURVES OF TYPE FA-6-A AIR FAN (SWEEP BLADE, 30 in. pitch variable)

erating by no means now, having been considered in a variety of forms for propellers for a number of years. The greatest difficulty in actual construction has been that the mechanical strength necessary to withstand the very high centrifugal forces and the durability of operation necessary for close regulation are very hard to obtain.

The objective, however, applies as forcibly to fans using very thin blades, which are expected to warp under centrifugal action to change the pitch and a few samples tested when it was hoped would operate on this principle were tested. They were unsuccessful principally on account of insufficient strength and the impossibility of getting a smooth surface. The method is as far as of doubtful utility, since it can probably take care of only limited variations in speed, whereas the pivoted-blade fans are capable of regulating over the whole variation in air speed likely to be met with in engine practice.

Pivoted-Blade Air Fans. The earliest pivoted-blade fan to receive the attention of the Endeavor Development Section was made by the Eddy Gyroscope Company, but it proved unsuccessful, due to mechanical weakness. It was, however, the forerunner of very successful fans and serves to illustrate the general principles of which to operate. The fan was mounted on bearings and was capable of rotating through a definite angle. Centrifugal weights are mounted on arms al-

FIG. 9. TYPE FA-6-VARIABLE-PITCH AIR FAN, SWEEP BLADE.

tached to these blades and tend to turn them to the proper direction to increase the pitch. A rotating spring and screw-spring hub complete the mechanism.

The first model to perform satisfactorily was designed by

Mr. Thomas State, of the American Mechanical Improvement Company, of Washington, D. C. The very great improvement over the first-blade fan then in use made the production of this fan highly desirable, and it was undertaken at once under purchase specifications as follows:

Operating diameter (in.)	44 or more
Blade radius (in.)	30 or more
Unloaded fan	3000 ft/min

It was, of course, realized that this fan was by no means in its final form and work continued improving it until a reasonably new series of production was carried out as rapidly as possible. One of the objections to the original design was that the particular mechanism used caused the rated air flow to increase as the rate of twist, the angle, while the spring resistance force increased, causing a straight-line relationship. The original design was improved by the use of a spiral linkage between spring and blade, which simplified the series of spring resistance to that of the centrifugal weight. Fig. 7 shows one of these fans and Fig. 8 its performance. It was, as in many other cases of radio development, work done in secret, and the information given by the Raymond Gyroscopic Company and the Edwards Research and Manufacturing Company is in a form ready for immediate publication.

The third successful design of variable-pitch air fan was the work of Mr. Parsons of the Dux Laboratories Aircraft Company, and differs very markedly from those previously

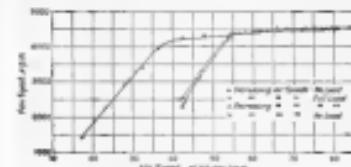

FIG. 10. PERFORMANCE CURVES OF TYPE FA-6 AIR FAN (SWEEP BLADE, 30 in. pitch variable)

described. It uses only one blade and its principal advantage is that by application of aerodynamic principles all strain is taken off the bearing, whereas in other forms the thrust bearing must carry a very considerable load—both radial and thrust—due to the high speed of rotation and the unbalanced design of the blades. Further, no motor is used, and it operates "dead" in the center of the fan. The constructional features of the Parsons fan is also a considerable improvement over its predecessors in simplicity and ease of manufacture. Figs. 9 and 10 show its construction and performance.

Bend-Rubber Tires

A demonstration of the value of the regulating air fans in reducing head resistance was made in the first test of a complete radio-telegraph transmitting set in the wind tunnel. A prop was first made with the set equipped with a fan hub and nose cap, but no blades; then a second prop was made with a fan operating normally with the generator hub loaded and running light, and finally a third prop was made with the fan hub loaded and the generator off gear. The results of these tests are shown in Fig. 11, from which the following conclusions may be drawn:

The head resistance of the fan fully loaded in air streams of 25 miles per hour is 2.5 lb. At this air speed the resistance of the blades alone equals the head resistance of the body, after which the resistance of the blades increases more rapidly, while that of the body increases as the square of the air

speed. The body alone has 9 lb. head resistance at an air speed of 90 miles per hour, and at the speed ratio 5 to 3, from the engine prop 10 lb. of head resistance, this requires 0.65 h.p. from the engine. On a basis of 25 lb. in the fairings per h.p. from the engine, the air speed would be 100 miles per hour, and the prop will be 10 lb. in head load, the engine required to drive it would be 0.5 h.p. in the fairings and obtained its power directly from the engine. This emphasizes the disadvantage already mentioned of obtaining all electric power by direct drive to do so.

Direct Fans on Blades for Regulating Air Fans. In designing blades for regulating air fans the effect of wind pressure in producing torque around the blade axis has been appreciated, and obviously such an effect might seriously interfere with the performance of the fan. To obtain data on the point tests were made on blades from a fan of the type shown in Fig. 1, and the results are as follows:

The results thus obtained show that this effect is negligible as far as practical designing is concerned.

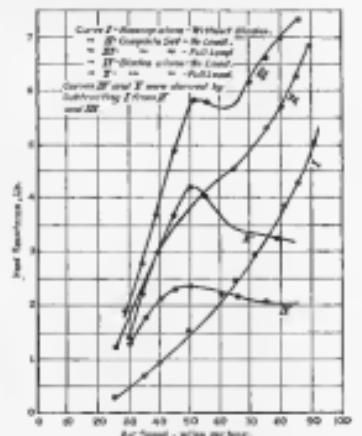

FIG. 11. HEAD-RESISTANCE CURVES, TYPE FA-6, AIR FAN

The Fan of the R-38

On Oct. 22, in the House of Commons, Lord-Gen. Mountbatten asked whether Great Britain had made any arrangements with the American government for the building of a radio station in Scotland for the United States Navy.

Mr. Grey-Taylor, Minister of War, replied that no arrangements had been made between the United States Navy and the Air Ministry by which the airship R-38 would be employed to supply the radio station. The vessel will be based over Scotland, and the radio station will be maintained on completion, and will proceed to America with her American crew as soon as the need to house her in ready.

French Practice in Airship Construction

Abstract by John Jay Ide, Lt. (j.g.), U. S. N. R. F.

Experiments for designs of airships.—Envelope fabric woven 16 in. at 10 mm. stitching is in two rows 1/8 in. apart; strips or right angles are used. The envelope is made of two layers of fabric woven 16 in. wide of same color as exterior of envelope in connected over entire areas.

One single-ply raw white leather strip 1 1/2 in. wide is connected over interior areas. The strip is coated with aluminum paint on the side next to seam. Over this is connected another strip 1 1/2 in. wide of single-ply fabric. This is reinforced on top with a strip of single-ply fabric. It is reinforced on the bottom with a strip of single-ply fabric. The strip is 1 1/2 in. wide and 1/8 in. thick.

In later balloons only one exterior strip is used, but this is of 2 in. width. The envelope fabric envelope 16 in. instead of 10 in. The two rows of stitching, however, remain 1/8 in. apart.

Each successive strip has its width and weight, parallel and perpendicular, respectively, to its length, whereas the envelope has broadened very much. (See Fig. 1.)

Provisional Tubes Against Explosions When Filling Hydrogen.—Following are instructions for filling hydrogen tubes. (1) After filling, the pressure must be released in the balloon envelope before the gas cylinders are connected. (2) If no connection is made with the gas cylinders, the envelope must be evacuated.

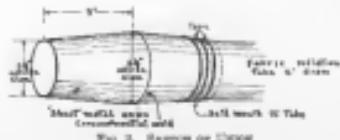

After the hydrogen cylinders are connected to the balloon through copper tubes, manifold and radiation tray, observe the following order of operations to empty the cylinders. First open the valves on the manifold bottom. Then close the main manifold valve. Third open the valves on the gas cylinders.

After cylinders are connected to be empty within two minutes, and thus Fig. 2. Shut the main manifold valve. Second shut the valve on the cylinder. Third open the valve. Thus the valve on the gas cylinder. Do not touch anything.

If the pressure drops below three-tenths of an atm., empty at three other cylinders. If the pressure continues to fall, empty the other three cylinders.

The objects of the precautions taken in filling cylinders are to prevent the entry of air and hydrogen to prevent explosive mixture and to avoid the reduced life of gas caused with atm. (4) Elimination of fire hazard.

These objects are attained by: 1. General plant layout. 2. Design of isolating lead and connections. 3. Design of metal lead and connections. 4. Protection of gas cylinders. 5. Protection with fabric, isolating lead and connections. 6. Protection with compressed hydrogen cylinders. 7. Electric lights and switches. 8. Conduct of personnel. 9. Fire-quenching means.

As to general layout there are two French schools of practice. In one the manifold is placed at a distance from the

hangar, the fabric filling tube being from 350 to 380 ft. long. The idea is that in case of fire at the manifold the fire may not reach the hangar and vice versa. In the other school the filling tube is as short as possible, so the theory is that with proper precautions fire hazard is eliminated and that a long filling tube is likely to take in more air at connections, etc. than a short tube. In either case the manifold is placed outside the hangar.

The fabric isolating lead is about 8 in. in diameter and very slightly bell-shaped at the ends where attached to connections. Only one isolating lead is used. End caps are slightly tapered so that the fabric will fit the isolating lead and it over these caps the isolating lead tightens with each stroke for a couple of inches of length. (See Fig. 2.)

The manifold, of the simplest possible type, is of solid cast iron or bronze with six branches. The inside diameter is about 8 in. The dead end of this manifold should be closed to a small cavity or weathervane port. The main body of the manifold is described as follows: The end of the manifold is provided with a simple, but positive, man valve. Each of the six manifold branches and each hydrogen cylinder is provided with a valve smaller than that on the cylinder. The body of the manifold is made of solid cast iron. Small plates, copper tubes (3/16 to 6 in. in diameter), connecting the manifold to isolating leads, through suitable joints, with the hydrogen cylinders.

The envelope is fastened out as much as possible before inflation so that there is no surplus.

After the envelope tube has been connected up it is flattened as much as possible. The hydrogen gas which is connected with a tube to the fire hazard, would escape through the crevices in the tube to the fire hazard, or would be adsorbed by means of exterior retinae and diffusion, increasing the life of the dirigible. (See Fig. 3.)

Prior to inflation, large, strong stays are threaded, or after completion of inflation, tubes left unconnected, but should be safely tied up at appropriate and convenient

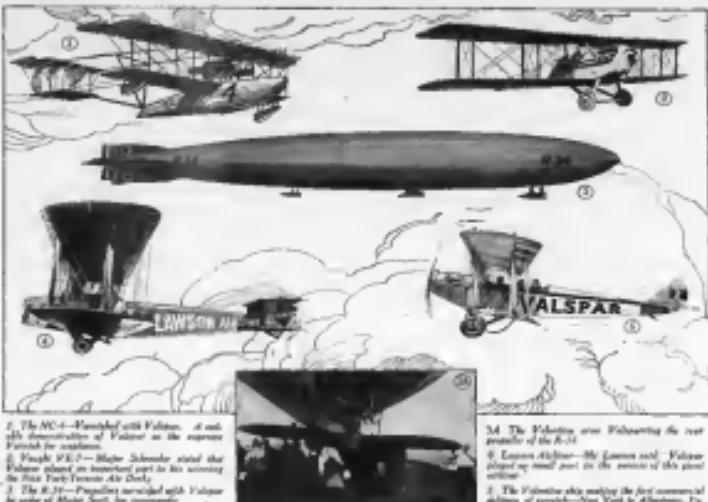

The hydrogen cylinder valve are never opened, except when hydrogen is taken away from manifold. If they were opened, the escaping hydrogen, expanding, would be a real explosion. After filling, the hydrogen cylinder is turned around so that the valve is at the bottom. The hydrogen should be exhausted until when cylinder are empty their valves must be closed, and remain so to avoid presence of air in rest of cylinder.

The hangar is illuminated by incandescent electric lights protected against fire hazard in the most approved way. All electric wires to the lights should be outside the main hangar hall, separated therefore by a wall.

The usual precautions such as non-smoking, no carriage of matches, etc., are observed by those working in the hangar. In addition, it is desirable that incense burners kept in boxes be used. The incense should be placed in a box and held in the pocket while being worn on and off.

Open bags of dry sand are placed next to the inflation tube at its junction with the manifold and its entrance to the hangar. In case of fire or other accident the bag can be placed directly on the tube, thus flattening it and sealing off the opening, also holding at the same time.

Properties of Gas.—All metal parts of the tube equipment are sep-

The world's famous aircraft are Valspared

THROUGHOUT the great war, Valspur saw service as the varnish for the airplanes of America and the Allied Governments. During the past year the activities of peace have produced many notable aerial achievements, in all of which Valspur has played an important part.

Valspur's toughness, elasticity and waterproofness have made good in every trial of war and peace. It is the one varnish that can be absolutely depended upon under all conditions of air service.

santed from the bag by a distance of from 3 to 6 ft., where attached to the bag they are suspended by cords of vegetable fiber giving such a grip.

Metal parts used inside the balloon, as in valves, etc., are designed so no intermittent contacts are made. There must be no gaps between metal parts, nor must any electric charge easily be transferred. The parts of metal inside the balloon, must be in extremely good electrical contact, if they are in contact at all.

These precautions are laid down by the manufacturer of the airship. Other precautions are prescribed by the radio authorities.

Suspended vs. Drift-type of Balloons.—The latter type is preferable.

Objects in suspended type: (1) The balloon tends to float at point of suspension, therefore it must be made of heavier material than the drift-type.

(2) Repair of the balloon is difficult, as an upper part can be reached by a man inside.

(3) The suspended apparatus tends to deform the top of the main envelope.

Advantages of drift-type.

(1) It is in tendency to tear, therefore a light fabric may be used.

(2) It is a simple matter.

(3) There is no deformation of main envelope.

(4) There is less deflating surface, hence less material and again a lighter balloon.

(5) When empty, the thickness of two fabrics at the bottom of the envelope is about the same. The gas and atmosphere.

To prevent the shifting of the balloon longitudinally a system of stay stays is used.

In the case of long balloons, transverse non-rotatable silk curtains perforated with 1-in. holes are used. These curtains are attached to the top of the balloon and free from the envelope. They do not impede the even distribution of air into all compartments of the balloon on its change of volume, but they are effective in preventing surge of the air mass.

Stand vs. Water vs. Balloon.—Water is preferable to balloon for the reasons that it is safe, has a large surface and other advantages with a possibility of serious damage.

The objection with water may dispose, it may be replied that a great part of the time services are given up under conditions where that may take place. If the accident does go into the water, the water will not penetrate the glass or glycerine, but may get into the water to lower the freezing point. Salt should never be used as an antifreeze of balloon, etc.

Even sand, however, is preferable to land or other solid land, as an amount of damage done to the terrain by the latter, thus, of course, does not apply to beams or balloon when over sandy terrain.

Noticing for Independent Heavy Fuel.—An independent burner and an independent burner for a small auxiliary, on which

tional air may be added when the balloon is deflating, when another a main motor take-off over a ventilator system can be used.

At 3 to 4 hp, gasoline burner engine is recommended for a small auxiliary. In addition, there should be a ventilating funnel and tube, the function of which is to push out the main burner fumes and prevent them from the main burner.

For an airship of about 250,000 cu. ft., the main power plant should be in two or three units. Each of these units should be provided with a safety check and breaker, to insure reliability.—*Technical Note.* Bureau of Construction and Repair, Navy Department.

Air Mail Record

All load-carrying air planes records for the postal mail service are broken on Dec. 2 when a trans-Atlantic De Havilland 4-plane delivered the first mail received from the Post Office Department. The distance between the mail office at Washington and that at Belmont Park, New York, a distance of 218 miles in 1 hour, 26 minutes, with a mail load of nearly 30,000 letters weighing 850 pounds. The speed was at the rate of 138 miles per hour. The last previous record was on Sept. 18, when a mail plane from the Hawaiian Islands to San Francisco, Calif., Washington to New York at a speed of 133 miles per hour and the third mail record was on October 1 when a Curtis plane carried 388 pounds from New York to Washington at a speed of 121 miles per hour.

The latest record (De Havilland today) was set by Standard A. H. Plant, Jr., of Princeton, Pa., and Bell College Park at 12 A. M. arriving at Belmont Park at 12:34 P. M. The time of flight included two circles around the field for altitude before setting out on his course and was the first trip made by the plane on a regular carrying of the mail. The plane is powered by a 12-cylinder Pratt & Whitney R-1830 engine which not only maintains the altitude under full load with ease, but actually climbs on one engine. In the opinion of the postal authorities it is the greatest forward step made in the development of a mail-carrying plane. It eliminates the dependence of a single mail-carrying plane. It eliminates the need of carrying the mail in a separate car or van from the gasoline supplies and also it minimizes danger to the pilot for the same reason. The trans-Atlantic De Havilland is a distinctive product of the postal service being purchased principally by the Bureau of Postmaster General Otto Koenig. The first mail delivery record was worked out by Mr. A. H. Plant, College Park, Md.

The plane will enable the Department to adapt several hundred thousands of dollars worth of the Standard 4 to mail and parts as well as labor motions, the power plant being the most important of the new type. The plane has been constructed almost entirely out of one life-cycle, 480 hp Liberty. The plane can carry nearly double the mail load that is carried by the single motor De Havilland.

HALL-SCOTT

Hall-Scott Type 10 Airplane Engine
Major General H. J. Hall, upon the orders of the Secretary of War as shown in War Department General Orders No. 10, dated March 1928, was awarded the contract for the manufacture of the Hall-Scott Type 10 Airplane Engine. This engine is the standard power plant of the Liberty engine and is manufactured in the workshop of the Hall-Scott Corporation in the American methods of production and assembly. The Hall-Scott Type 10 is the most powerful engine ever built in America.

The more facts that liberal-minded men in public association with our country, reading no action taken in the design and production of Hall-Scott Airplane engines can be made known to important countries than they will receive a present outlet up to the world market.

JONES

AIRPLANE TACHOMETER

"Best by Test"

was designed especially for the United States Navy Department for use in the war.

We supplied this Navy Department with large quantities of these instruments and their splendid record of success under all conditions was demonstrated by the famous Trans-Atlantic flight of the N.C. 1 - N.C. 2 - N.C. 4 where the JONES AIRPLANE TACHOMETERS were standard equipment, having been highly commended by the Navy Department officials.

The mechanism is of the centrifugal type; the dial is black with radian graduations and pointer, and is calibrated in various speed ranges up to 3000 R. P. M.

JONES AIRPLANE TACHOMETER

is the lightest instrument of any type yet produced, and is geared to be driven at own shaft or engine speed without extra attachment.

JONES HAND TACHOMETER

Carry one and you can make R. P. M. quickly, easily and accurately. It is believed to be the lightest absolute power plant, preserving data, etc., in aircraft engines, that ever has been made. It is made of aluminum and precision, with uniformly spaced dial, with handsome silvered case.

Send today for a copy of our "JONES AIRPLANE TACHOMETER" catalog.

Micrograph of section of Lynite-Piston showing the greatest diversity of metal.

Micrograph of section of piston made from some alloy 100-kg sand-casting process.

The Camera Doesn't Lie

To the eye, two aluminum alloy pistons may look just about alike, but put them under the searching gaze of the microscope and surprising differences are likely to appear.

The differences shown are micrographs of sections of two pistons, one made by the ordinary sand-casting process, the other by the pressure-sand process, used in making Lynite-Pistons.

The same alloy was used in each case and the two cast pistons look almost identical. The difference is taken here at a glance; we see how much finer the grain and more closely tied the structure of the pressure-sand piston.

The fine-grained structure is due to the rapid cooling during solidification which results in a better dispersion of the copper aluminum alloy. Through the greater number of small pores prior to the skin, the energy-poor gases and around the ring

govern. Another surprising advantage of Lynite-Pistons is their lower heat loss, resulting in a saving of fuel and time.

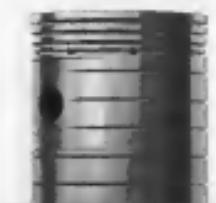

Lynite-Pistons also have a number of advantages in manufacturing. Less metal has to be removed in machining because they are lighter and more dimensionally stable.

Freedom from heat spots makes possible greater machining speed because little trouble is encountered with cracked tools and burrs.

Greater economy and efficiency, faster cooling time to be reported.

Absence of blow-holes and dimensional defects also play a considerable part in cutting down the cost of manufacturing parts, reducing machining time and tool, and speeding up production.

ROLAND ROHLS AND THE CURTISS "WASP"

"Farthest Up"

THE internationally famous Curtiss "Wasp" Triplane—established the world's record on September 18 by attaining a height of 34,610 feet—more than six miles in the air, guided by Roland Rohlfs, test-pilot.

"Farthest North" and "Farthest South" have been attained by brave explorers, but "Farthest Up" mastery of the air—has constantly tempted human skill and courage.

Curtiss achievement has brought us "nearest the sun" of aircraft-perfection. The recognized safety and efficiency of Curtiss products result from the highest ideals and constant scientific efforts towards perfection.
